

OPA166x 低消費電力、低ノイズおよび低歪、バイポーラ入力、SoundPlus™ オーディオ オペアンプ

1 特長

- 低ノイズ: 1kHz で $3.3\text{nV}/\sqrt{\text{Hz}}$
- 低歪: 1kHz 時に 0.00006%
- 小さい静止電流:
1.5mA (チャンネルあたり)
- スルーレート: $17\text{V}/\mu\text{s}$
- 広いゲイン帯域幅: 22MHz (G = +1)
- ユニティゲイン安定
- レール ツー レール出力
- 広い電源電圧範囲:
 $\pm 1.5\text{V} \sim \pm 18\text{V}$ または $3\text{V} \sim 36\text{V}$
- デュアルおよびクワッドのバージョンで供給
- 小型のパッケージ
デュアル: SOIC-8、VSSOP-8
クワッド: SOIC-14、TSSOP-14

2 アプリケーション

- USB および FireWire オーディオ システム
- アナログ/デジタル ミキサ
- ポータブル レコーディング システム
- オーディオ エフェクト プロセッサ
- ハイエンド A/V レシーバ
- ハイエンド DVD および Blu-Ray™ プレーヤ
- ハイエンド カー オーディオ

3 概要

デュアル OPA1662 およびクワッド OPA1664 (OPA166x) バイポーラ入力 SoundPlus™ オーディオ オペアンプ シリーズは、 $3.3\text{nV}/\sqrt{\text{Hz}}$ の低ノイズ密度と 0.00006% (1kHz 時) の超低歪みを実現しています。OPA166x オペアンプ シリーズは、 $2\text{k}\Omega$ の負荷で 600mV 以内のレール ツー レール出力が可能のため、ヘッドルームが増大し、ダイナミック レンジが最大化されます。これらのデバイスは、 $\pm 30\text{mA}$ の高い出力駆動能力も持っています。

これらのデバイスは $\pm 1.5\text{V} \sim \pm 18\text{V}$ または $3\text{V} \sim 36\text{V}$ の非常に広い範囲の電源電圧において、チャンネルごとにわずか 1.5mA の消費電流で動作します。OPA166x オペアンプは、ユニティゲインにおいて安定であり、幅広い負荷条件にわたって優れた動的挙動を示します。

これらのデバイスは完全に独立した回路を使用しているため、オーバードライブまたは過負荷時でも、クロストークが最小限に抑えられ、チャンネル間干渉が発生しません。

OPA166x は、 $-40^\circ\text{C} \sim +85^\circ\text{C}$ で動作が規定されています。

6.1 Application Information

The OPA166x are unity-gain stable, precision dual and quad op amps with very low noise. Applications with noisy or high-impedance power supplies require decoupling capacitors close to the device pins. In most cases, 0.1 μ F capacitors are adequate. 図 6-1 shows a simplified schematic of the OPA166x (one channel shown).

6.1.1 Operating Voltage

The OPA166x series op amps operate from ± 1.5 V to ± 18 V supplies while maintaining excellent performance. The OPA166x series can operate with as little as 3V between the supplies and with up to 36V between the supplies. However, some applications do not require equal positive and negative output voltage swing. With the OPA166x series, power-supply voltages do not need to be equal. For example, set the positive supply to 25V with the negative supply at -5 V.

In all cases, the common-mode voltage must be maintained within the specified range. In addition, key parameters are specified over the specified temperature range of $T_A = -40^\circ\text{C}$ to $+85^\circ\text{C}$. Parameters that vary significantly with operating voltage or temperature are shown in the [Typical Characteristics](#).

図 6-1. OPA166x Simplified Schematic

6.1.2 Input Protection

The input terminals of the OPA166x are protected from excessive differential voltage with back-to-back diodes, as [Figure 6-2](#) illustrates. In most circuit applications, the input protection circuitry has no consequence. However, in low-gain or $G = +1$ circuits, fast ramping input signals can forward bias these diodes because the output of the amplifier cannot respond rapidly enough to the input ramp. If the input signal is fast enough to create this forward bias condition, the input signal current must be limited to 10mA or less. If the input signal current is not inherently limited, an input series resistor (R_I), a feedback resistor (R_F), or both, can be used to limit the signal input current. This resistor degrades the low-noise performance of the OPA166x and is examined in [Section 6.1.3](#). [Figure 6-2](#) shows an example configuration when both current-limiting input and feedback resistors are used.

Figure 6-2. Pulsed Operation

6.1.3 Noise Performance

[Figure 6-3](#) shows the total circuit noise for varying source impedance values with the op amp in a unity-gain configuration (no feedback resistor network, and therefore no additional noise contributions).

The OPA166x (GBW = 22MHz, $G = +1$) is shown with total circuit noise calculated. The op amp contributes both a voltage noise component and a current noise component. The voltage noise is commonly modeled as a time-varying component of the offset voltage. The current noise is modeled as the time-varying component of the input bias current and reacts with the source resistance to create a voltage component of noise. Therefore, the lowest noise op amp for a given application depends on the source impedance. For low source impedance, current noise is negligible, and voltage noise generally dominates. The low voltage noise of the OPA166x series op amps makes them a better choice for low source impedances of less than 1k Ω .

The equation in [Figure 6-3](#) shows the calculation of the total circuit noise, with these parameters:

- e_n = Voltage noise
- i_n = Current noise
- R_S = Source impedance
- k = Boltzmann's constant = 1.38×10^{-23} J/K
- T = Temperature in kelvins (K)

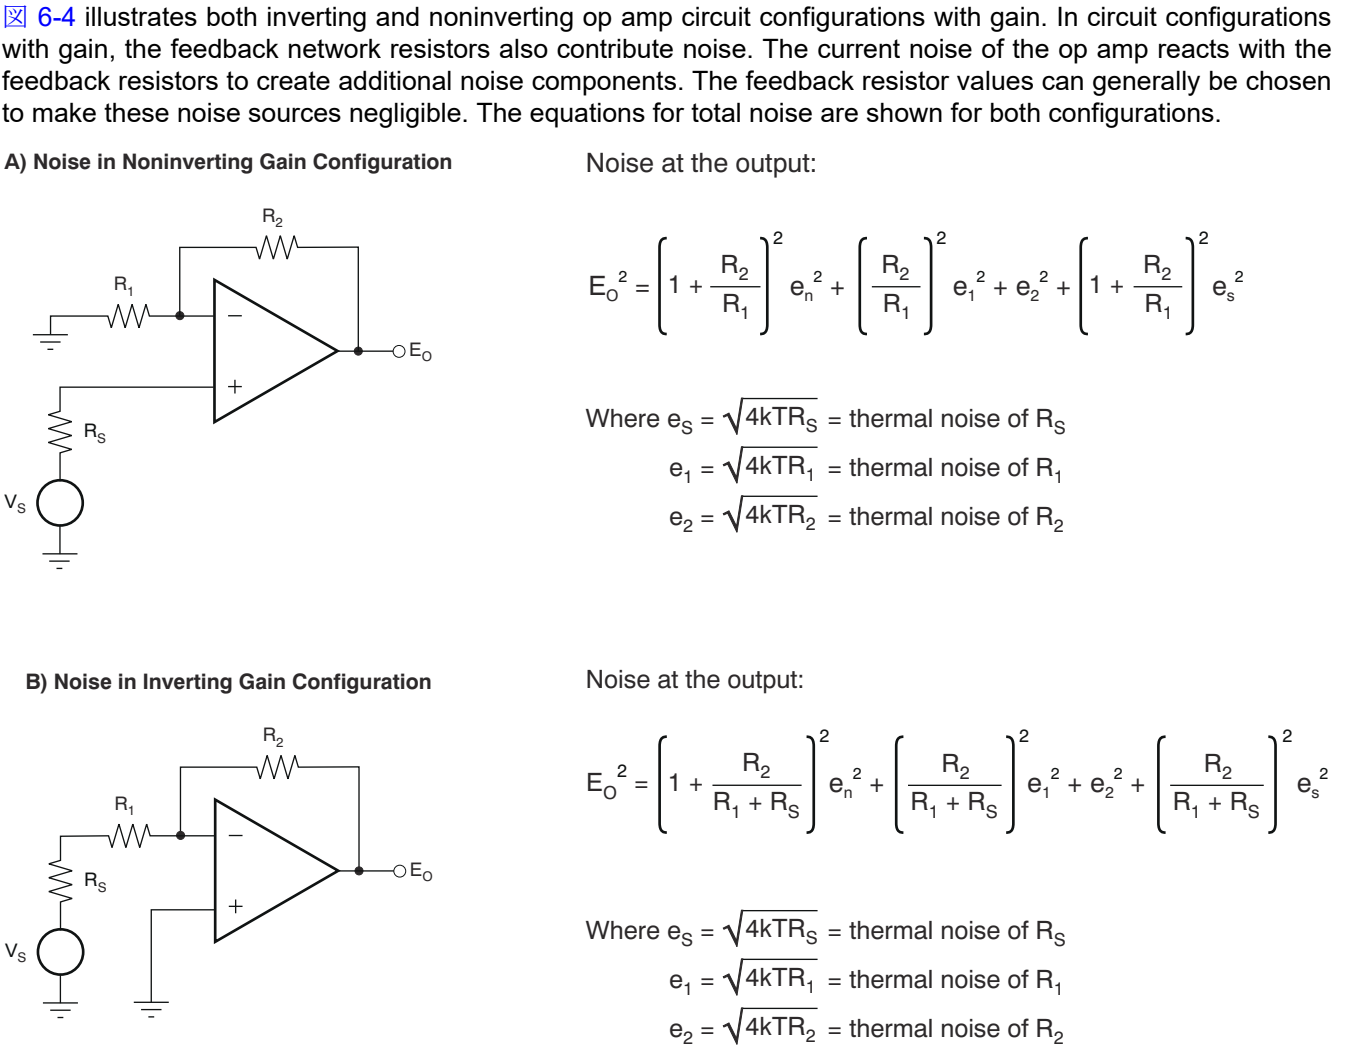

Figure 6-3. Noise Performance of the OPA166x in Unity-Gain Buffer Configuration

6.1.4 Basic Noise Calculations

Design of low-noise op amp circuits requires careful consideration of a variety of possible noise contributors: noise from the signal source, noise generated in the op amp, and noise from the feedback network resistors. The total noise of the circuit is the root-sum-square combination of all noise components.

The resistive portion of the source impedance produces thermal noise proportional to the square root of the resistance.  6-3 plots this equation. The source impedance is usually fixed; consequently, select the op amp and the feedback resistors to minimize the respective contributions to the total noise.

 6-4 illustrates both inverting and noninverting op amp circuit configurations with gain. In circuit configurations with gain, the feedback network resistors also contribute noise. The current noise of the op amp reacts with the feedback resistors to create additional noise components. The feedback resistor values can generally be chosen to make these noise sources negligible. The equations for total noise are shown for both configurations.

A) Noise in Noninverting Gain Configuration

Noise at the output:

$$E_o^2 = \left(1 + \frac{R_2}{R_1}\right)^2 e_n^2 + \left(\frac{R_2}{R_1}\right)^2 e_1^2 + e_2^2 + \left(1 + \frac{R_2}{R_1}\right)^2 e_s^2$$

Where $e_s = \sqrt{4kTR_s}$ = thermal noise of R_s

$e_1 = \sqrt{4kTR_1}$ = thermal noise of R_1

$e_2 = \sqrt{4kTR_2}$ = thermal noise of R_2

B) Noise in Inverting Gain Configuration

Noise at the output:

$$E_o^2 = \left(1 + \frac{R_2}{R_1 + R_s}\right)^2 e_n^2 + \left(\frac{R_2}{R_1 + R_s}\right)^2 e_1^2 + e_2^2 + \left(\frac{R_2}{R_1 + R_s}\right)^2 e_s^2$$

Where $e_s = \sqrt{4kTR_s}$ = thermal noise of R_s

$e_1 = \sqrt{4kTR_1}$ = thermal noise of R_1

$e_2 = \sqrt{4kTR_2}$ = thermal noise of R_2

For the OPA166x series of op amps at 1kHz, $e_n = 3.3\text{nV}/\sqrt{\text{Hz}}$.

 6-4. Noise Calculation in Gain Configurations

6.1.5 Total Harmonic Distortion Measurements

The OPA166x series op amps have excellent distortion characteristics. THD + noise is below 0.0006% (G = +1, V_O = 3V_{RMS}, BW = 80kHz) throughout the audio frequency range, 20Hz to 20kHz, with a 2kΩ load (see [Figure 5-7](#) for characteristic performance).

The distortion produced by the OPA166x series op amps is below the measurement limit of many commercially available distortion analyzers. However, a special test circuit (such as [Figure 6-5](#) shows) can be used to extend the measurement capabilities.

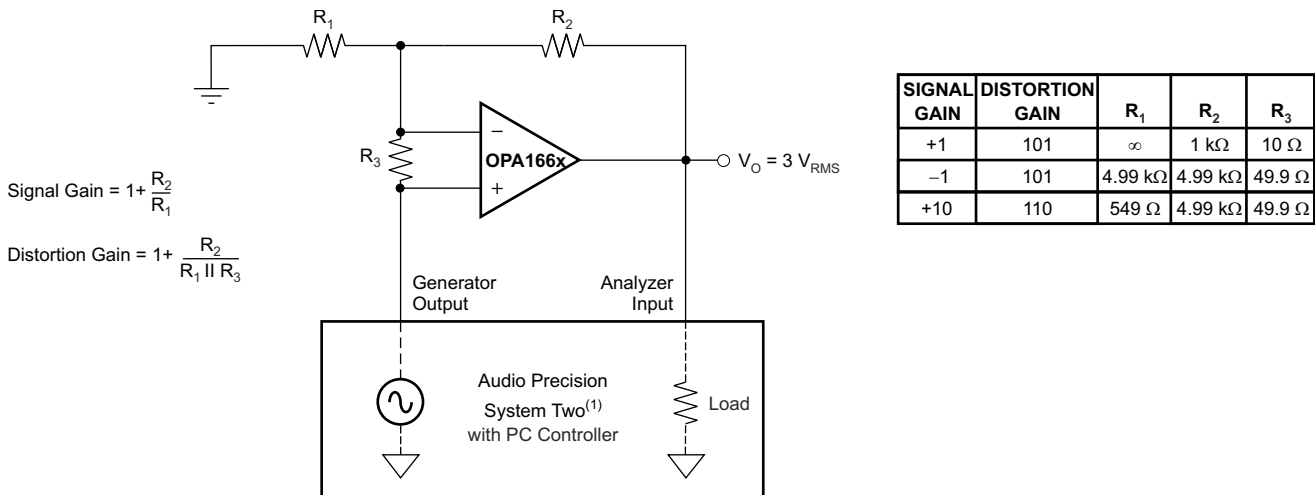

Op amp distortion is considered an internal error source that is referred to the input. [Figure 6-5](#) shows a circuit that causes the op amp distortion to be gained up (refer to the table in [Figure 6-5](#) for the distortion gain factor for various signal gains). The addition of R₃ to the otherwise standard non-inverting amplifier configuration alters the feedback factor or noise gain of the circuit. The closed-loop gain is unchanged, but the feedback available for error correction is reduced by the distortion gain factor, thus extending the resolution by the same amount. Note that the input signal and load applied to the op amp are the same as with conventional feedback without R₃. The value of R₃ must be kept small to minimize the effect on the distortion measurements.

The validity of this technique can be verified by duplicating measurements at high gain and/or high frequency where the distortion is within the measurement capability of the test equipment. Measurements for this data sheet were made with an Audio Precision System Two distortion/noise analyzer, which greatly simplifies such repetitive measurements. The measurement technique can, however, be performed with manual distortion measurement instruments.

6.1.6 Capacitive Loads

The dynamic characteristics of the OPA1662 and OPA1664 have been optimized for commonly encountered gains, loads, and operating conditions. The combination of low closed-loop gain and high capacitive loads decreases the phase margin of the amplifier and can lead to gain peaking or oscillations. As a result, heavier capacitive loads must be isolated from the output. The simplest way to achieve this isolation is to add a small resistor (R_S equal to 50Ω, for example) in series with the output.

This small series resistor also prevents excess power dissipation if the output of the device becomes shorted. [Figure 5-25](#) illustrates a graph of *Small-Signal Overshoot vs Capacitive Load* for several values of R_S. Also, refer to [Applications Bulletin AB-028](#) (literature number SBOA015, available for download from the TI web site) for details of analysis techniques and application circuits.

6.1.7 Power Dissipation

The OPA1662 and OPA1664 series op amps are capable of driving 2kΩ loads with a power-supply voltage up to ±18V and full operating temperature range. Internal power dissipation increases when operating at high supply voltages. Copper leadframe construction used in the OPA166x series op amps improves heat dissipation compared to conventional materials. Circuit board layout can also help minimize junction temperature rise. Wide copper traces help dissipate the heat by acting as an additional heat sink. Temperature rise can be further minimized by soldering the devices to the circuit board rather than using a socket.

6.1.8 Electrical Overstress

Designers often ask questions about the capability of an operational amplifier to withstand electrical overstress. These questions tend to focus on the device inputs, but can involve the supply voltage pins or even the output pin. Each of these different pin functions have electrical stress limits determined by the voltage breakdown characteristics of the particular semiconductor fabrication process and specific circuits connected to the pin. Additionally, internal electrostatic discharge (ESD) protection is built into these circuits to protect them from accidental ESD events both before and during product assembly.

A good understanding of this basic ESD circuitry and the relevance to an electrical overstress event is important.  6-6 illustrates the ESD circuits contained in the OPA166x (indicated by the dashed line area). The ESD protection circuitry involves several current-steering diodes connected from the input and output pins and routed back to the internal power-supply lines, where the diodes meet at an absorption device internal to the operational amplifier. This protection circuitry is intended to remain inactive during normal circuit operation.

An ESD event produces a short duration, high-voltage pulse that is transformed into a short duration, high-current pulse when discharging through a semiconductor device. The ESD protection circuits are designed to provide a current path around the operational amplifier core to prevent the amplifier from being damaged. The energy absorbed by the protection circuitry is then dissipated as heat.

When an ESD voltage develops across two or more of the amplifier device pins, current flows through one or more of the steering diodes. Depending on the path that the current takes, the absorption device can activate. The absorption device internal to the OPA166x triggers when a fast ESD voltage pulse is impressed across the supply pins. Once triggered, the ESD cell quickly activates, clamping the ESD pulse to a safe voltage level.

When the operational amplifier connects into a circuit such as that illustrated in  6-6, the ESD protection components are intended to remain inactive and not become involved in the application circuit operation. However, circumstances can arise where an applied voltage exceeds the operating voltage range of a given pin. During this condition, there is a risk that some of the internal ESD protection circuits can be biased on, and conduct current. Any such current flow occurs through steering diode paths and rarely involves the absorption device.

 6-6 depicts a specific example where the input voltage, V_{IN} , exceeds the positive supply voltage ($+V_S$) by 500mV or more. Much of what happens in the circuit depends on the supply characteristics. If $+V_S$ can sink the current, one of the upper input steering diodes conducts and directs current to $+V_S$. Excessively high current levels can flow with increasingly higher V_{IN} . As a result, the data sheet specifications recommend that applications limit the input current to 10mA.

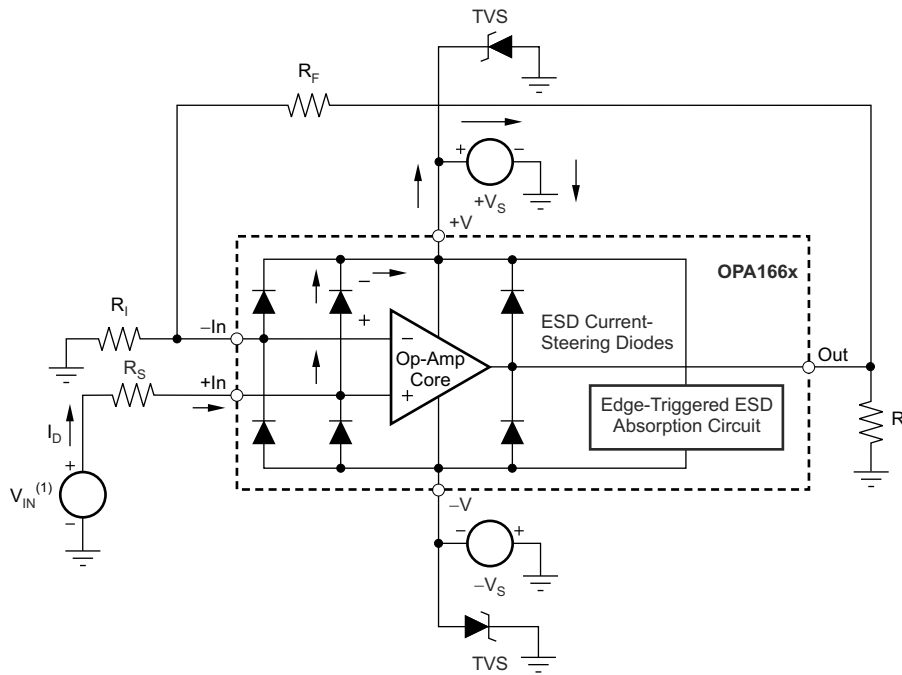

If the supply is not capable of sinking the current, V_{IN} can begin sourcing current to the operational amplifier, and then take over as the source of positive supply voltage. The danger in this case is that the voltage can rise to levels that exceed the operational amplifier absolute maximum ratings. In extreme but rare cases, the absorption device triggers on while $+V_S$ and $-V_S$ are applied. If this event happens, a direct current path is established between the $+V_S$ and $-V_S$ supplies. The power dissipation of the absorption device is quickly exceeded, and the extreme internal heating destroys the operational amplifier.

Another common question involves what happens to the amplifier if an input signal is applied to the input while the power supplies $+V_S$ and/or $-V_S$ are at 0V. This also depends on the supply characteristic while at 0V, or at a level below the input signal amplitude. If the supplies appear as high impedance, then the operational amplifier supply current can be supplied by the input source via the current steering diodes. This state is not a normal bias

condition; the amplifier does not operate normally. If the supplies are low impedance, then the current through the steering diodes can become quite high. The current level depends on the ability of the input source to deliver current, and any resistance in the input path.

If there is an uncertainty about the ability of the supply to absorb this current, external zener diodes can be added to the supply pins as shown in 6-6.

The zener voltage must be selected such that the diode does not turn on during normal operation. However, the zener voltage must be low enough so that the zener diode conducts if the supply pin begins to rise above the safe operating supply voltage level.

(1) $V_{IN} = +V_S + 500mV$.
